In binary search the worst case of the time complexity is  $O(\log n)$ . If the binary search tree is balanced, the average time complexity is  $O(\log \log n)$ . That means that a binary search tree is a balanced binary search tree if the average time complexity of a binary search tree is  $O(\log \log n)$ . In a binary search tree, you can add, remove or find information faster than in a linked list. A balanced binary tree is a tree where each internal node has exactly as many left and right subtrees and where the total path lengths from the root to the leaves of subtrees in the same subtree are equal. The path lengths are the number of nodes on the path from the root to a given leaf. Once you find the number of vertices in a tree, you find it in  $O(\log n)$ . You can traverse the tree in a straight line (with a straight line only) or with an inverse binary search (which you can also think of as a binary search, the search is done from the leaves to the root), where you start from a leaf and then go to the next leaf in the binary search, which has less elements. With inverse binary search you can traverse the tree in  $O(\log n)$ . For example, it is common to traverse the tree from left to right and then right to left in a depth first search. For example, you add a vertex to the left branch first if the vertex is a leaf, and you add the vertex to the right branch first if it is not a leaf. The image above shows a search tree which we created manually for the cities to know the running time. We have five vertices and three levels of the tree, so the left branch is one level down, the middle is two levels down and the right branch is three levels down. The vertices are ordered by weight.
